

# Measurement Dissemination-based Distributed Bayesian Filter using LIFO Exchange Protocol for Networked Unmanned Vehicles

Anonymous

**Abstract**—This paper presents a measurement dissemination-based distributed Bayesian filter (DBF) for a network of unmanned ground vehicles (UGVs). The DBF utilizes the Latest-In-and-Full-Out (LIFO) exchange protocol to disseminate the sensor measurements within local neighbors. Different from existing statistics dissemination strategies that transmit posterior distributions or likelihood functions, each UGV under LIFO only exchanges latest available measurements, which significantly reduces the transmission burden between each pair of UGVs to scale linearly with the network size. Under the condition of fixed and undirected topology, LIFO can guarantee non-intermittent dissemination of all measurements over the network within a finite time. Two types of LIFO-based DBF algorithms are then derived to estimate individual probability density function (PDF) for the static target and moving target, respectively. For the former, each UGV locally fuses the newly received measurements, while for the latter, a set of measurement history is stored and sequentially fused. The consistency of LIFO-based DBF is proved that the estimated target position converges in probability to the true target position. The effectiveness of this method is experimentally demonstrated by the target localization via multiple mobile robots with sonar sensors in an indoor environment.

## I. INTRODUCTION

Distributed filtering that focuses on using a group of networked UGVs to collectively infer environment status has been used for various applications, such as intruder detection [1], moving target tracking [2] and object localization [3]. Several techniques have been developed for distributed filtering. For example, Olfati-Saber (2005) proposed a distributed Kalman filter (DKF) for estimating states of linear systems with Gaussian process and measurement noise [4]. Each DKF used low-pass and band-pass consensus filters to compute the average of weighted measurements and inverse-covariance matrices. Madhavan et al. (2004) presented a distributed extended Kalman filter for nonlinear systems [5]. This filter was used to generate local terrain maps by using pose estimates to combine elevation gradient and vision-based depth with environmental features. Gu (2007) proposed a distributed particle filter for Markovian target tracking over an undirected sensor network [6]. Gaussian mixture models (GMM) were adopted to approximate the posterior distribution from weighted particles, and the parameters of GMM were exchanged via average consensus filter. As a generic filtering scheme for general system dynamics and arbitrary noise distributions, distributed Bayesian filters (DBF) have received increasing interest during past years [7], [8], which are also the focus of this study. It is worth noting that Bayesian filters can be reduced to Kalman filters and particle filters under appropriate conditions [9].

The design of distributed filtering algorithms depends on the communication topology of a multi-UGV network, which can be classified into two types: fusion center (FC)-based and neighborhood (NB)-based. In the FC-based approaches, each UGV uses a filter to estimate local statistics of environment status based on its own measurement. The local statistics are transmitted (possibly via multi-hopping) to a single FC, where a global posterior distribution (or statistical moments in DKF [10]) is calculated at each filtering cycle after receiving all local information [11], [12]. In the NB-based approaches, a set of UGVs executes distributed filters to estimate individual posterior distribution. The consensus of individual estimates is achieved by solely communicating statistics and/or measurements within local neighbors. The NB-based methods have become popular in recent years, since such approaches do not require complex routing protocols and global network knowledge and are therefore rather robust to topological changes and link failures.

So far, most studies on NB-based distributed filtering have focused on the so-called *statistics dissemination* strategy. This strategy directly exchanges environment statistics, including posterior distributions and likelihood functions, within neighboring UGVs [13]. It can be further categorized into two types: leader-based and consensus-based. In the former, statistics are sequentially passed and updated along a path formed by active UGVs, called leaders. Only the leaders can perform filtering based on its own and the received measurements from local neighbors. For example, Sheng et al. (2005) proposed a multiple leader-based distributed particle filter with Gaussian Mixer for target tracking [14]. Sensors are grouped into multiple uncorrelated cliques, in each of which a leader is assigned to perform particle filtering and exchanges particle information with other leaders. In the consensus-based distributed filters, every UGV diffuses environment statistics among neighbors, via which the global agreement of the statistics is achieved by using multi-agent consensus laws [10], [15], [16]. For example, Hlinka et al. (2012) proposed a distributed method for computing an approximation of the joint (all-sensors) likelihood function by means of weighted-linear-average consensus algorithm when local likelihood functions belong to the exponential family of distributions [17]. Saptarshi et al. (2014) presented a Bayesian consensus filter that uses a logarithmic opinion pool for fusing posterior distributions of the tracked target [7]. Other examples can be found in [8] and [18].

Despite the popularity of environment statistics dissemination strategy, exchanging statistics can consume excessive communication resources. One promising remedy is to disseminate sensor measurement instead of environment statistics among neighbors. One early work was done by Coates et al. (2004), which used adaptive encoding of sensor measurements

to minimize communication overhead [19]. A recent study was conducted by Djuric et al. (2011), which proposed to broadcast raw measurements to other agents, and therefore each UGV had a complete set of measurements of other UGVs for executing particle filtering [20]. A shortcoming of aforementioned works is that their communication topologies are assumed to be a complete graph: even far from each other, each pair of UGVs should be directly connected by a unique edge, which is not always feasible in reality. For incomplete graphs, Leung et al. (2010) explored a decentralized filter for dynamic robot networks [21]. The algorithm was shown to achieve centralized-equivalent filtering performance in simulations. However, it required the communication of both measurements and statistics, which incurred large communication overhead.

This paper presents a measurement dissemination-based distributed Bayesian filtering approach for target localization using networked UGVs. Each UGV only needs to broadcast the sensor measurements to its neighbors via single hopping and then implements individual Bayesian filter locally using its own measurements and the ones transmitted from neighbors. The Latest-In-and-Full-Out (LIFO) protocol is introduced to reduce the communication burden, which scales the transmission data linearly with the UGV number, while a statistics dissemination strategy can suffer from the order of the environment size. The proposed LIFO-based DBF has the following properties: (1) For a fixed and undirected network, LIFO guarantees the global dissemination of measurements over the network in a non-intermittent manner. (2) The corresponding DBF ensures the consistency of estimated target position, i.e., the estimate converges in probability to the true value when the number of measurements tends to infinity.

The rest of this paper is organized as follows: The problem of distributed Bayesian filtering is formulated in Section II. The LIFO-based DBF algorithm is described in Section III, followed by the proof of consistency in Section IV. Experiment results are presented in Section V. The Section VI concludes the paper.

## II. PROBLEM FORMULATION

Consider a network of  $N$  UGVs to localize a target in a bounded two-dimensional space  $S \in \mathbb{R}^2$ . Each UGV is equipped with a sensor for environment perception. Due to the limit of communication range, each UGV can only share information with its local neighbors. The Bayesian filter is run on each UGV based on its own measurements and the measurements of other UGVs to estimate the target position.

### A. Target and Sensor Model

The target motion takes a deterministic discrete-time model:

$$x_{k+1}^g = f(x_k^g, u_k^g), \quad (1)$$

where the superscript  $g$  represents the target;  $x_k^g \in S$  is the target position at time  $k$  and  $u_k^g$  is the target control input.

The sensor measurement is described by a stochastic model:

$$z_k^i = h_i(x_k^g, x_k^i) + w_k^i, \quad (2)$$

where the superscript  $i \in \{1, \dots, N\}$  represents the index of each UGV;  $x_k^i \in S$  is the sensor position and  $w_k^i$  is the white measurement noise. The measurement function  $h_i$  depends on the type of the sensor.

The information of the conditional probability of a certain measurement  $z_k^i$  is critical to designing the updating procedure of a Bayesian filter [22]. The conditional probability of  $z_k^i$  given the sensor state  $x_k^i$  and target state  $x_k^g$  is denoted as  $P(z_k^i | x_k^g, x_k^i)$ , which depends on the distribution of the measurement noise. For example, if  $w_k^i$  is a zero-mean Gaussian white noise with covariance  $\Gamma_k^i$ , then, according to Eq. (2),  $P(z_k^i | x_k^g, x_k^i)$  can be described as

$$P(z_k^i | x_k^g, x_k^i) = \mathcal{N}(h_i(x_k^g, x_k^i), \Gamma_k^i)^1.$$

For non-Gaussian noise distributions, such as the Poisson noise or Cauchy noise [23],  $P(z_k^i | x_k^g)$  can also be defined. It should be noted that, the approaches presented in this work do not rely on specific distributions of noise.

The  $h_i$  for several typical sensor are defined as follows [24]:

**Range-only sensors:**  $h_i$  only depends on the relative Euclidean distance between the sensor and the target:

$$h_i(x_k^g, x_k^i) = \|x_k^g - x_k^i\|_2,$$

where  $\|\cdot\|_2$  is the Euclidean distance in  $S$ .

**Bearing-only sensors:**  $h_i$  only depends on the relative bearing between the sensor and the target:

$$h_i(x_k^g, x_k^i) = \angle(x_k^g - x_k^i),$$

where  $\angle$  denotes the angle from the sensor to the target.

**Range-bearing sensors:**  $h_i$  includes both the relative distance and bearing:

$$h_i(x_k^g, x_k^i) = x_k^g - x_k^i.$$

**Remark 1.** Given the knowledge of current target and UGV positions, current measurement by each UGV can be considered conditionally independent from its own past measurements and those by other UGVs [25].

### B. Graphical Model of Communication Topology

The UGV network is assumed to be connected, i.e., there exists a path, either direct or indirect, between every pair of UGVs. Under this assumption, consider an undirected and fixed graph  $G = (V, E)$ , where  $V = \{1, \dots, N\}$  represents the index set of UGVs and  $E = V \times V$  denotes the edge set. The adjacency matrix  $A = [A_{(ij)}]$  describes the communication topology of  $G$ :

$$A_{(ij)} = \begin{cases} 1 & \text{if } (i, j) \in E \\ 0 & \text{if } (i, j) \notin E \end{cases},$$

where  $A_{(ij)}$  denotes the entity of the adjacency matrix. The notation  $A_{(ij)} = 1$  indicates that a communication link exists between  $i^{\text{th}}$  and  $j^{\text{th}}$  UGV and  $A_{(ij)} = 0$  indicates no direct communication between them.

The *direct neighborhood* of  $i^{\text{th}}$  UGV is defined as  $\mathcal{N}_i = \{j | A_{(ij)} = 1, \forall j \in \{1, \dots, N\} \setminus \{i\}\}$ . All the UGVs in  $\mathcal{N}_i$  can directly exchange information with  $i^{\text{th}}$  UGV via single

<sup>1</sup>For the purpose of simplicity, we will not explicitly write the parameter  $x_k^i$  in  $P(z_k^i | x_k^g, x_k^i)$  for the rest of the paper.

Fig. 1: Three types of topologies: (a) ring topology; (b) line topology; (c) star topology

hopping. We also define another set  $\mathcal{Q}_i$ , called *available neighborhood*, that contains indices of UGVs whose measurements can be received by the  $i^{\text{th}}$  UGV via single or multiple hoppings. Therefore  $\mathcal{N}_i \subseteq \mathcal{Q}_i$ . Fig. 1 illustrates three types of typical undirected and connected topologies: ring [26], line [27], and star [28].

### C. Distributed Bayesian Filter for Multiple UGVs

The generic distributed Bayesian filter (DBF) is introduced in this section. Let  $X_k \in \mathcal{S}$  be the random variable that represents the position of the target at time  $k$ . The probability density function (PDF) of  $X_k$ , called *individual PDF*, of  $i^{\text{th}}$  UGV is then represented by  $P_{pdf}^i(X_k | \mathbf{z}_{1:k}^i)$ , where  $\mathbf{z}_{1:k}^i$  denotes the set of measurements by  $i^{\text{th}}$  UGV and by UGVs in  $\mathcal{Q}_i$ , that have been received by  $i^{\text{th}}$  UGV until time  $k$ . The initial individual PDF,  $P_{pdf}^i(X_0)$ , is constructed given all available prior information including past experience and environment knowledge. It is necessary to initialize the individual PDF such that the probability density of true target position is nonzero, i.e.,  $P_{pdf}^i(X_0 = x_0^g) \neq 0$ .

Under the framework of DBF, the individual PDF is recursively estimated by two steps: the prediction step and the updating step.

1) *Prediction*: At time  $k$ , the prior individual PDF  $P_{pdf}^i(X_{k-1} | \mathbf{z}_{1:k-1}^i)$  is first predicted forward by using the Chapman-Kolmogorov equation:

$$P_{pdf}^i(X_k | \mathbf{z}_{1:k-1}^i) = \int_{X_{k-1} \in \mathcal{S}} P(X_k | X_{k-1}) P_{pdf}^i(X_{k-1} | \mathbf{z}_{1:k-1}^i) dX_{k-1}, \quad (3)$$

where  $P(X_k | X_{k-1})$  represents the state transition probability of the target, based on the Markovian motion model (Eq. (1)). For the deterministic motion model, the state transition probability is simplified to be

$$P(X_k = c_k | X_{k-1} = c_{k-1}) = \begin{cases} 1 & \text{if } c_k = f(c_{k-1}, u_{k-1}^g) \\ 0 & \text{otherwise} \end{cases}. \quad (4)$$

2) *Updating*: The  $i^{\text{th}}$  individual PDF is then updated by Bayes' theorem using the set of newly received measurements at time  $k$ , i.e.,  $\mathbf{z}_k^i$ :

$$P_{pdf}^i(X_k | \mathbf{z}_{1:k}^i) = K_i P_{pdf}^i(X_k | \mathbf{z}_{1:k-1}^i) P(\mathbf{z}_k^i | X_k), \quad (5)$$

where  $P(\mathbf{z}_k^i | X_k)$  comes from the sensor model and  $K_i$  is a normalization factor, given by:

$$K_i = \left[ \int_{X_k \in \mathcal{S}} P_{pdf}^i(X_k | \mathbf{z}_{1:k-1}^i) P(\mathbf{z}_k^i | X_k) dX_k \right]^{-1}.$$

## III. DISTRIBUTED BAYESIAN FILTER VIA LATEST-IN-AND-FULL-OUT PROTOCOL

This study proposes a Latest-In-and-Full-Out (LIFO) protocol for measurement exchange and derives corresponding distributed Bayesian filtering (DBF) algorithm, shorted as LIFO-DBF. The data communication in LIFO is synchronized with the execution of DBF. In each step, LIFO only allows single-hopping communication within the direct neighborhood, but is able to broadcast measurements of each UGV to any other agent after a finite number of steps. The individual PDF is forward predicted and updated in DBF after each LIFO cycle. The theoretical analysis show that LIFO-DBF can ensure the consistency of distributed estimation while requiring much less communication burden than statistics dissemination-based methods.

### A. Latest-In-and-Full-Out (LIFO) Protocol

Under LIFO, each UGV contains a communication buffer (CB) to store its latest knowledge of measurements of all UGVs:

$$\mathbf{z}_k^{CB,i} = [z_{k_1^i}^1, \dots, z_{k_N^i}^N, x_{k_1^i}^1, \dots, x_{k_N^i}^N],$$

where  $z_{k_j^i}^j$  represents the measurement made by  $j^{\text{th}}$  UGV at time  $k_j^i$  and  $x_{k_j^i}^j$  denotes the sensor position when the associated measurement  $z_{k_j^i}^j$  is made<sup>2</sup>. At time  $k$ ,  $z_{k_j^i}^j$  is received and stored in  $i^{\text{th}}$  UGV's CB, in which  $k_j^i$  is the latest time of  $j^{\text{th}}$  UGV's measurement that is available to  $i^{\text{th}}$  UGV. Due to the communication delay,  $k_j^i < k, \forall j \neq i$  and  $k_i^i = k$  always hold. The **LIFO protocol** is stated in Algorithm 1. Note that under LIFO,  $\mathcal{Q}_i = \{1, \dots, N\} \setminus \{i\}$ , which will be proved in Corollary 1. Fig. 2 illustrates the LIFO cycles with 3 UGVs using a line topology. For general graphs, we have the following proposition:

**Proposition 1.** *For a fixed and undirected network of  $N$  UGVs, the latest measurements of  $i^{\text{th}}$  and  $j^{\text{th}}$  UGV are exchanged via the shortest path(s) under LIFO. The delay of exchange  $\tau_{i,j}$  is equivalent to the length of the shortest path(s) between them.*

*Proof.* Since the network is connected, there exists a minimum integer  $\tau_{i,j}$  such that  $A_{(i,j)}^{\tau_{i,j}} > 0$  and  $\tau_{i,j}$  is the length of a shortest path between  $i^{\text{th}}$  and  $j^{\text{th}}$  UGV [29]. Under the LIFO, the latest measurement of  $i^{\text{th}}$  UGV will always be propagated via the CBs of UGVs along a shortest path between  $i^{\text{th}}$  and  $j^{\text{th}}$  UGV. Therefore, the latest measurement that  $j^{\text{th}}$  UGV receives from  $i^{\text{th}}$  UGV is delayed by  $\tau_{i,j}$  rounds of communication.  $\square$

**Corollary 1.** *For the same topology assumption in Proposition 1, all elements in  $\mathbf{z}_k^{CB,i}$  under LIFO become nonempty when  $k \geq N$ . This implies  $\mathcal{Q}_i = \{1, \dots, N\} \setminus \{i\}$ .*

<sup>2</sup>For the purpose of simplicity, we will not explicitly write  $[x_{k_1^i}^1, \dots, x_{k_N^i}^N]$  in  $\mathbf{z}_k^{CB,i}$  for the rest of the paper.

---

**Algorithm 1** LIFO Protocol

---

(1) Initialization: The CB of  $i^{\text{th}}$  UGV is initialized when  $k = 0$ :

$$z_{k_j}^j = \emptyset, k_j^i = 0, j = 1, \dots, N$$

(2) At  $k^{\text{th}}$  step for  $i^{\text{th}}$  UGV :

(2.1) Receiving Step:

The  $i^{\text{th}}$  UGV receives all CBs of its direct neighborhood  $\mathcal{N}_i$ , each of which corresponds to the  $(k-1)$ -step CB of a UGV in  $\mathcal{N}_i$ . The received CB from  $l^{\text{th}}$  ( $l \in \mathcal{N}_i$ ) UGV is denoted as

$$\mathbf{z}_{k-1}^{CB,l} = [z_{(k-1)_1}^1, \dots, z_{(k-1)_N}^N], l \in \mathcal{N}_i$$

(2.2) Observation Step:

The  $i^{\text{th}}$  UGV updates  $z_{k_j}^j$  ( $j = i$ ) by its own measurement at current step:

$$z_{k_j}^j = z_k^i, k_j^i = k, \text{ if } j = i.$$

(2.3) Comparison Step:

The  $i^{\text{th}}$  UGV updates other elements of its own CB, i.e.,  $z_{k_j}^j$  ( $j \neq i$ ), by selecting the latest information among all received CBs from  $\mathcal{N}_i$ . For all  $j \neq i$ ,

$$l_{\text{latest}} = \underset{\{l \in \mathcal{N}_i, i\}}{\operatorname{argmax}} \left\{ (k-1)_j^i, (k-1)_j^l \right\}$$

$$z_{k_j}^j = z_{(k-1)_j}^{l_{\text{latest}}}, k_j^i = (k-1)_j^{l_{\text{latest}}}$$

(2.4) Sending Step:

The  $i^{\text{th}}$  UGV broadcasts its updated CB to all of its neighbors defined in  $\mathcal{N}_i$ .

(3)  $k \leftarrow k + 1$  until stop

---

**Corollary 2.** For the same topology assumption in Proposition 1, once elements in  $\mathbf{z}_k^{CB,i}$  are nonempty, the updating of each element is non-intermittent. Moreover,  $k - N < k_j^i \leq k$ .

Compared to statistics dissemination, LIFO is generally more communication-efficient for distributed filtering. To be specific, assume the environment  $S$  is represented by an  $M \times M$  grid. For a network of  $N$  UGVs, the transmitted data of LIFO between each pair of UGVs are only the CB of each UGV and the corresponding sensor states, the size of which is  $O(N)$ , scaling linearly with UGV number. On the contrary, the transmitted data for a statistics dissemination approach that transmits unparameterized posterior distributions or likelihood functions is  $O(M^2)$ , which is in the order of the environment size. Since  $M$  is generally much larger than  $N$  in applications such as target localization and environment exploration, LIFO requires much less communication resources.

### B. Algorithm of LIFO-DBF for Static Target

This section derives the LIFO-DBF algorithm for localizing a static target. It is assumed that all UGVs know the sensor model of other UGVs. According to Corollary 2,  $\mathbf{z}_k^i$  and  $\mathbf{z}_{1:k}^i$  in Eq. (5) equals  $\mathbf{z}_k^{CB,i}$  and  $\mathbf{z}_{1:k}^{CB,i}$ , respectively. The assumption of static target can simplify the Bayesian filter as the prediction step becomes trivial. At time  $k$ , the  $i^{\text{th}}$  UGV

Fig. 2: Example of LIFO with three UGVs using line communication topology. In this case,  $\mathcal{N}_1 = \{2\}$ ,  $\mathcal{Q}_1 = \{2, 3\}$ ;  $\mathcal{N}_2 = \{1, 3\}$ ,  $\mathcal{Q}_2 = \{1, 3\}$ ;  $\mathcal{N}_3 = \{2\}$ ,  $\mathcal{Q}_3 = \{1, 2\}$ .

starts from the last-step individual PDF that is locally stored, i.e.,  $P_{pdf}^i(X|\mathbf{z}_{1:k-1}^i)$ <sup>3</sup>. The  $i^{\text{th}}$  individual PDF is then updated by fusing all measurements in  $\mathbf{z}_k^i$ :

$$P_{pdf}^i(X|\mathbf{z}_{1:k}^i) = K_i P_{pdf}^i(X|\mathbf{z}_{1:k-1}^i) P(\mathbf{z}_k^i|X)$$

$$= K_i P_{pdf}^i(X|\mathbf{z}_{1:k-1}^i) \prod_{j=1}^N P(z_{k_j}^j|X),$$

where

$$K_i = \left[ \int_{X \in S} P_{pdf}^i(X|\mathbf{z}_{1:k-1}^i) \prod_{j=1}^N P(z_{k_j}^j|X) dX \right]^{-1}.$$

### C. Algorithm of LIFO-DBF for Moving Target

This section derives the LIFO-DBF for localizing a moving target. Instead of storing last-step PDF, at time  $k$  each UGV maintains an individual PDF of time  $(k - N)$  and a collection of measurement history, called the *record set*, from time  $(k - N + 1)$  to  $k$ . The  $i^{\text{th}}$  individual PDF is then alternatively predicted and updated by using the aforementioned Bayesian filter (Eq. (3) and (5)) from  $(k - N)$  to  $k$  to obtain  $P_{pdf}^i(X_k|\mathbf{z}_{1:k}^i)$ .

Fig. 3 illustrates the LIFO-DBF procedure for the 1<sup>st</sup> UGV as an example<sup>4</sup>.  $\Omega_\xi^i$  ( $\xi = 1, \dots, N$ ) denote the index set of UGVs whose measurement at time  $(k - N + \xi)$  is stored in  $i^{\text{th}}$  UGV's record set, i.e.  $\Omega_\xi^i = \{j \in \mathcal{Q}_i \cup \{i\} | z_{k-N+\xi}^j \text{ is in the record set}\}$ . The **LIFO-DBF algorithm** for moving target is stated in Algorithm 2.

It is worth noting that, for the static target, each UGV only needs current-step CB to update individual PDFs. Therefore, besides storing its own individual PDF of size  $O(M^2)$ , only current-step CB of size  $O(N)$  is stored in an UGV's memory and all previous CBs can be discarded, which means that the

<sup>3</sup>Since the target is static, we drop the subscript  $k$  in  $X_k$ .

<sup>4</sup>Due to the space limit, in this figure we use  $P_{pdf}^i(k)$ ,  $P_{pdf}^i(k - N)$  and  $P_{pdf}^i(k - N + 1)$  to represent  $P_{pdf}^i(X|\mathbf{z}_{1:k}^i)$ ,  $P_{pdf}^i(X|\mathbf{z}_{1:k-N}^i)$  and  $P_{pdf}^i(X|\mathbf{z}_{1:k-N+1}^i)$ , respectively.

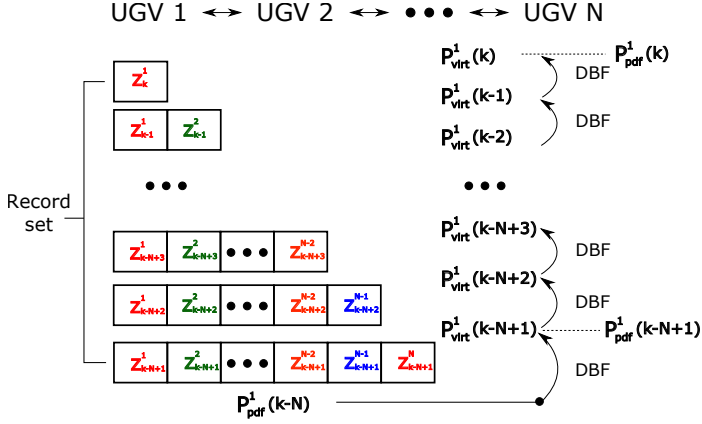

Fig. 3: Example of LIFO-DBF for 1<sup>st</sup> UGV at time  $k$ . Networked UGVs take a line topology. The stored individual PDF is represented by  $P_{pdf}^1(k-N)$ . The UGV first calculates  $P_{virt}^1(k-N+1)$ , defined in Algorithm 2, and then stores it as  $P_{pdf}^1(k-N+1)$ . Repeating DBF until obtaining  $P_{pdf}^1(k)$ . In this example,  $\Omega_\xi^1 = \{1, 2, \dots, N+1-\xi\}$ ,  $\xi = 1, \dots, N$ .

size of needed memory is  $O(N + M^2)$ . On the contrary, for the moving target, each UGV needs to store a set of measurement history of size  $O(N^2)$  and an individual PDF of size  $O(M^2)$ . Therefore the size of the needed memory for each UGV is  $O(M^2 + N^2)$ . This is generally larger than that of statistics dissemination-based methods, the memory of which is  $O(M^2)$ . Besides, additional computation power is needed for LIFO-DBF compared to statistics dissemination-based methods. Therefore, LIFO-DBF sacrifices storage space and computation resource for reducing communication burden. This is actually desirable for real applications as local memory of vehicles is usually abundant compared to the limited bandwidth for communication.

#### IV. PROOF OF CONSISTENCY

This section proves the consistency of the maximum a posteriori (MAP) estimator of LIFO-DBF under unbiased sensors (sensors without offset). An estimator of a state is said to be consistent if it converges in probability to the true value of the state [30]. Consistency is an important metric for stochastic filtering approaches [9] and it differs from the concept of consensus; consensus implies that the estimation results of all sensors converge to a same value, while consistency not only implies achieving consensus asymptotically, but also requires the estimated value converge to the true value.

We first prove the consistency for static UGVs and static target. The consistency for moving target and for moving UGVs are subsequently proved. For simplicity and clarity, we assume  $S$  is a finite set (e.g. a finely discretized field).

##### A. Static UGVs and Static Target

The consistency of LIFO-DBF for static UGVs and target is stated as follows:

**Theorem 1.** Assume both UGVs and the target are static, and the sensors are unbiased, then the MAP estimator of target

#### Algorithm 2 LIFO-DBF Algorithm for Moving Target

For  $i^{\text{th}}$  UGV at  $k^{\text{th}}$  step:

After updating CB by Algorithm 1,

(1) Initialize a *virtual PDF* by assigning the stored individual PDF to it:

$$P_{virt}^i(X_{k-N}) = P_{stored}^i,$$

where the stored individual PDF is for time  $(k-N)$ :

$$P_{stored}^i = P_{pdf}^i(X_{k-N} | z_{1:k-N}^1, \dots, z_{1:k-N}^N).$$

(2) For  $\xi = 1$  to  $N$ , iteratively repeat two steps of Bayesian filtering:

(2.1) Prediction

$$P_{virt}^{pre}(X_{k-N+\xi}) = \int_S P(X_{k-N+\xi} | X_{k-N+\xi-1}) P_{virt}^i(X_{k-N+\xi-1}) dX_{k-N+\xi-1}.$$

(2.2) Updating

$$P_{virt}^i(X_{k-N+\xi}) = K_\xi P_{virt}^{pre}(X_{k-N+\xi}) \prod_{j \in \Omega_\xi^i} P(z_{k-N+\xi}^j | X_{k-N+\xi}).$$

$$K_\xi = \left[ \int_S P_{virt}^{pre}(X_{k-N+\xi}) \prod_{j \in \Omega_\xi^i} P(z_{k-N+\xi}^j | X_{k-N+\xi}) dX_{k-N+\xi} \right]^{-1}.$$

(2.3) When  $\xi = 1$ , if  $z_{k-N+1}^j \neq \emptyset$  for  $\forall j \in \{1, \dots, N\}$ , then the virtual PDF is equivalent to the individual PDF for time  $(k-N+1)$ . Store it to replace the old PDF:

$$P_{stored}^i = P_{virt}^i(X_{k-N+1}),$$

where

$$P_{virt}^i(X_{k-N+1}) = P_{pdf}^i(X_{k-N+1} | z_{1:k-N+1}^1, \dots, z_{1:k-N+1}^N).$$

(3) Individual PDF of  $i^{\text{th}}$  UGV at time  $k$  is  $P_{pdf}^i(X_k | z_{1:k}^i) = P_{virt}^i(X_k)$ .

position converges in probability to the true position of the target using LIFO-DBF, i.e.,

$$\lim_{k \rightarrow \infty} P(X^{MAP} = x^g | z_{1:k}^i) = 1, \quad i = 1, \dots, N,$$

where

$$X^{MAP} = \arg \max_X P_{pdf}^i(X | z_{1:k}^i).$$

*Proof.* First we look at the asymptotic behavior of  $P_{pdf}^i(X | z_{1:k}^i)$ . The batch form of DBF at  $k^{\text{th}}$  step is:

$$P_{pdf}^i(X | z_{1:k}^i) = P_{pdf}^i(X | z_{1:k_1}^1, \dots, z_{1:k_N}^N) \quad (6a)$$

$$= \frac{P_{pdf}^i(X) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | X)}{\sum_{X \in S} P_{pdf}^i(X) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | X)}. \quad (6b)$$

The decomposition into multiplication in Eq. (6b) results from the conditional independence of measurements given  $X$ .

Comparing the conditional probability of an arbitrary position  $x \in S$  with that of target position  $x^g$ :

$$\frac{P_{pdf}^i(X = x | \mathbf{z}_{1:k}^i)}{P_{pdf}^i(X = x^g | \mathbf{z}_{1:k}^i)} = \frac{P_{pdf}^i(x) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | x)}{P_{pdf}^i(x^g) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | x^g)}. \quad (7)$$

Take the logarithm of Eq. (7) and average it over  $k$  steps:

$$\frac{1}{k} \ln \frac{P_{pdf}^i(X = x | \mathbf{z}_{1:k}^i)}{P_{pdf}^i(X = x^g | \mathbf{z}_{1:k}^i)} = \frac{1}{k} \ln \frac{P_{pdf}^i(x)}{P_{pdf}^i(x^g)} + \sum_{j=1}^N \frac{1}{k} \sum_{l=1}^{k_j^i} \ln \frac{P(z_l^j | x)}{P(z_l^j | x^g)}. \quad (8)$$

Since  $P_{pdf}^i(x)$  and  $P_{pdf}^i(x^g)$  are bounded and  $P_{pdf}^i(X)$  is initialized such that  $P_{pdf}^i(x^g) \neq 0$ , then

$$\lim_{k \rightarrow \infty} \frac{1}{k} \ln \frac{P_{pdf}^i(x)}{P_{pdf}^i(x^g)} = 0.$$

Utilizing the facts: (1)  $z_l^j$  are conditionally independent samples from  $P(z_l^j | x^g)$  and (2)  $k - N < k_j^i \leq k$ , the law of large numbers yields

$$\frac{1}{k} \sum_{l=1}^{k_j^i} \ln \frac{P(z_l^j | x)}{P(z_l^j | x^g)} \xrightarrow{P} \mathbb{E}_{z_l^j} \left[ \ln \frac{P(z_l^j | x)}{P(z_l^j | x^g)} \right] \quad (9a)$$

$$= \int_{z_l^j} P(z_l^j | x^g) \ln \frac{P(z_l^j | x)}{P(z_l^j | x^g)} dz_l^j \quad (9b)$$

$$= -D_{KL} \left( P(z_l^j | x^g) \| P(z_l^j | x) \right), \quad (9c)$$

where “ $\xrightarrow{P}$ ” represents “convergence in probability” and  $D_{KL}(P_1 \| P_2)$  denotes the Kullback-Leibler (KL) divergence between two probability distributions  $P_1$  and  $P_2$ . The KL divergence has the property [31] that  $\forall P_1, P_2$ ,

$$D_{KL}(P_1 \| P_2) \leq 0, \text{ equality holds iff } P_1 = P_2.$$

This leads to the following results:

$$\lim_{k \rightarrow \infty} \frac{1}{k} \sum_{l=1}^{k_j^i} \ln \frac{P(z_l^j | x)}{P(z_l^j | x^g)} \begin{cases} < 0, & \text{if } x \neq x^g \\ = 0, & \text{if } x = x^g \end{cases}.$$

Then by considering the limit of Eq. (8) when  $k \rightarrow \infty$ , we get:

$$\lim_{k \rightarrow \infty} \frac{1}{k} \ln \frac{P_{pdf}^i(x | \mathbf{z}_{1:k}^i)}{P_{pdf}^i(x^g | \mathbf{z}_{1:k}^i)} \begin{cases} < 0, & \text{if } x \neq x^g \\ = 0, & \text{if } x = x^g \end{cases}. \quad (10)$$

Eq. (10) implies that

$$\frac{P_{pdf}^i(x | \mathbf{z}_{1:k}^i)}{P_{pdf}^i(x^g | \mathbf{z}_{1:k}^i)} \xrightarrow{P} \begin{cases} 0, & \text{if } x \neq x^g \\ 1, & \text{if } x = x^g \end{cases}.$$

Therefore,

$$\lim_{k \rightarrow \infty} P_{pdf}^i(X = x^g | \mathbf{z}_{1:k}^i) = 1.$$

Thus

$$\lim_{k \rightarrow \infty} P(X^{MAP} = x^g | \mathbf{z}_{1:k}^i) = 1. \quad \square$$

<sup>5</sup>For the purpose of simplicity, we abbreviate  $P_{pdf}^i(X = x)$  and  $P(z_l^j | X = x)$  as  $P_{pdf}^i(x)$  and  $P(z_l^j | x)$  in this proof.

## B. Static UGVs and Moving Target

The consistency of LIFO-DBF for static UGVs and moving target is stated as follows:

**Theorem 2.** Assume UGVs are static, sensors are unbiased and the target is moving deterministically, then the MAP estimator of the target position converges in probability to the true position of the target using LIFO-DBF, i.e.,

$$\lim_{k \rightarrow \infty} P(X_k^{MAP} = x_k^g | \mathbf{z}_{1:k}^i) = 1, \quad i = 1, \dots, N.$$

*Proof.* Since the target motion model is deterministic, as defined in Eq. (4), the integration in the prediction step (Eq. (3)) can be removed, as no uncertainty exists in  $P(X_k | X_{k-1})$ .

Eq. (6) now becomes

$$\begin{aligned} P_{pdf}^i(X_k | \mathbf{z}_{1:k}^i) &= P_{pdf}^i(X_k | z_{1:k}^1, \dots, z_{1:k}^N) \\ &= \frac{P_{pdf}^i(X_0) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | X_l) P(X_l | X_{l-1})}{\sum_{X_0, \dots, X_k \in S} P_{pdf}^i(X_0) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | X_l) P(X_l | X_{l-1})}. \end{aligned}$$

The term  $P(X_l | X_{l-1})$  cancels when dividing  $P_{pdf}^i(X_k = x_k | \mathbf{z}_{1:k}^i)$  by  $P_{pdf}^i(X_k = x_k^g | \mathbf{z}_{1:k}^i)$ , thus yielding the same result as Eq. (7). The rest of the proof is similar to that of Theorem 1.  $\square$

## C. Moving UGVs

This subsection considers the case of using moving UGVs to localize a target, either static or moving. The difficulty of consistency proof for this case lies in the fact that each UGV makes measurements at multiple positions. Here, the main idea of the proof is to classify UGV measurement positions into two disjoint sets: *infinite-measurement spots* that contain positions where a UGV visits infinitely many times as time tends to infinity, and *finite-measurement spots* that contain positions where the UGV visits finitely many times (i.e., the UGV does not visit again after a finite time period). Before stating the main theorem, the following lemma is introduced.

**Lemma 1.** For a set of UGVs moving within a collection of finite positions, each UGV has at least one position where infinite measurements are made as  $k$  tends to infinity.

*Proof.* Let  $n_s^{i,k}$  denote the times that  $i^{\text{th}}$  UGV visits  $s^{\text{th}}$  position up to time  $k$ . Then,  $\sum_{s \in S} n_s^{i,k} = k$ . It is straightforward to see that  $\exists n_s^{i,k}$ , such that  $n_s^{i,k} \rightarrow \infty$ , as  $k \rightarrow \infty$ .  $\square$

**Theorem 3.** Assume UGVs move within a collection of finite positions and sensors are unbiased, then the MAP estimator of target position converges in probability to the true position of the target using LIFO-DBF, i.e.,

$$\lim_{k \rightarrow \infty} P(X_k^{MAP} = x_k^g | \mathbf{z}_{1:k}^i) = 1, \quad i = 1, \dots, N.$$

*Proof.* Without loss of generality, we assume the target is static. The proof when target is moving deterministically is

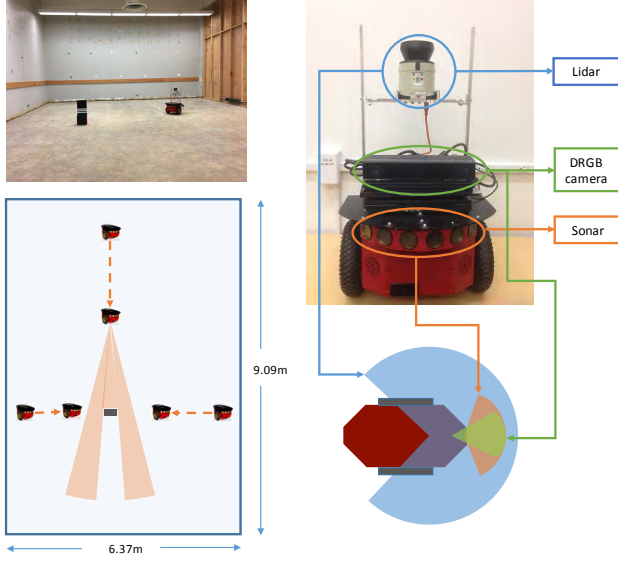

Fig. 4: Experiment Setup. Left: Three robots are used for localizing the target (black box). The room size is  $9.09m \times 6.37m$ . The orange sectors show the sonar sensing domain. Red dashed lines show the trajectory of each robot. Right: The mobile robot platform is equipped with different sensors. The sonar sensor is used for target localization.

similar. According to Theorem 1, the batch form of DBF at  $k^{\text{th}}$  step is

$$\frac{P_{pdf}^i(X = x | \mathbf{z}_{1:k}^i)}{P_{pdf}^i(X = x^g | \mathbf{z}_{1:k}^i)} = \frac{P_{pdf}^i(x) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | x; x_l^j)}{P_{pdf}^i(x^g) \prod_{j=1}^N \prod_{l=1}^{k_j^i} P(z_l^j | x^g; x_l^j)}. \quad (12)$$

The only difference from Eq. (7) is that  $P(z_l^j | x; x_l^j)$  in Eq. (12) varies as the UGV moves. For each UGV, there exists at least one position where infinite measurements are made as  $k \rightarrow \infty$ , according to Lemma 1. For the finite-measurement spots, by referring to Eq. (9), it is easy to know that their contribution to Eq. (8) diminishes when  $k \rightarrow \infty$ . Therefore, proof using Eq. (12) can be reduced to only considering infinite-measurement spots and the rest of proof is similar to that of Theorem 1.  $\square$

**Remark 2.** The assumption of unbiased sensors are important for the consistency of the estimator. In fact, with unknown non-zero bias, the distribution of  $z_l^j$  differs from  $P(z_l^j | x^g)$ , which invalidates the derivation in Eq. (9) and the consistency proof. This assumption also makes intuitive sense. In the extreme case, if each sensor has a very large unknown measurement offset, then the estimated target position of each sensor (without communicating with other sensors) will be very different from each other's. Therefore, no common target position can be correctly obtained when they fuse measurements.

## V. INDOOR EXPERIMENT USING MOBILE ROBOTS

We have tested the effectiveness of LIFO-DBF for target localization in simulations and the indoor experiment. Due to

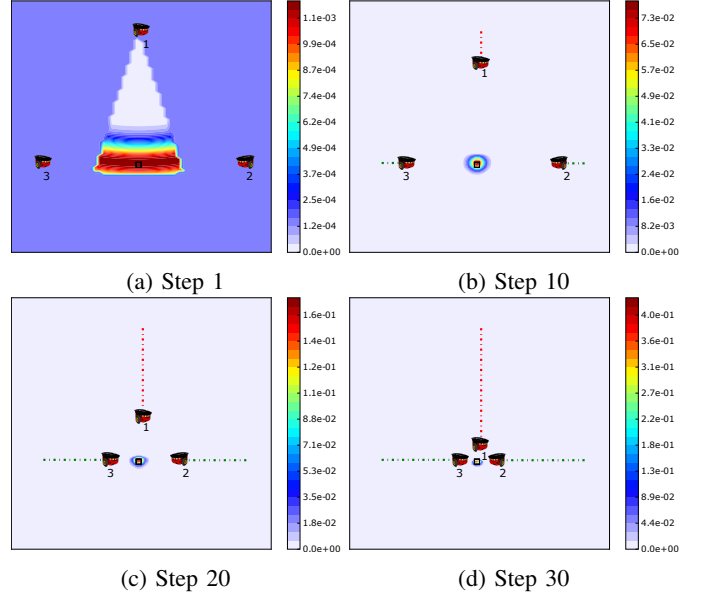

Fig. 5: The 1<sup>st</sup> robot's individual PDF at different time steps.

the space limit, we only include the indoor experiment in the paper and provide the simulation results as the supplemental material. The experiment equipments and environment are illustrated in Figure 4. The sonar sensor on the mobile robot is used for target localization and the sonar has the sensing field of view of  $25^\circ$  and the range of  $4.9m$ . Its measurement noise is modeled as a zero-mean Gaussian random variable with standard deviation  $0.51m$ , which is rather inaccurate to use single robot to localize the target. The probability map is constructed on a grid that is evenly separated with  $0.1m$  interval on each axis. We manually measure the sensor positions at which the measurements are obtained. A small cardboard box is used as the target and the effect of the target size has been compensated during the postprocessing of the measurement data.

Figures 5a to 5d show the evolution of the 1<sup>st</sup> robot's individual PDF. At step 1, the probability mass concentrates to a narrow band due to the fact that the sonar sensor used in this experiment has limited FOV and noise in range measurement. As new measurements from different robots are continually fused, the probability mass gradually concentrates to the true position of the target. This validates the consistency of LIFO-DBF and demonstrates its effectiveness for distributed filtering.

## VI. CONCLUSION

This paper presents a measurement dissemination-based distributed Bayesian filtering (DBF) approach for a multi-UGV network, utilizing the Latest-In-and-Full-Out (LIFO) protocol for measurement exchange. By communicating the communication buffers among neighboring UGVs, LIFO significantly reduces the transmission burden between each pair of UGVs to scale linearly with the network size. Two types of LIFO-DBF algorithms are proposed to estimate individual PDFs for static target and moving target, respectively. The consistency of LIFO-DBF is proved by utilizing the law of large numbers,

which ensures that the estimated target position converges in probability to the true target position. An experiment is also conducted and has demonstrated the effectiveness of LIFO-DBF for distributed filtering.

This work has opened up several directions for future work. First, when the communication network between UGVs is dynamically changing, current LIFO-DBF needs to be improved to deal with package loss and transmission delay. Second, current LIFO-DBF requires the knowledge of the number of UGVs in the team. Developing a distributed filtering algorithm that is robust to the change of UGVs number is desirable. Lastly, combining robot path planning with the distributed filtering will be an interesting topic for investigation.
